Embryonic mammary gland stem cells identified.

Publication in *Nature Cell Biology*: researchers at the Université Libre de Bruxelles, ULB define for the first time the mechanisms responsible for the mammary gland development.

The mammary gland is a tissue that produces the milk during lactation, allowing the survival of young mammalian offspring. The mammary gland is composed of two main lineages: the basal cells, which surround the inner luminal cells. The luminal cells can be subdivided into ductal cells, and alveolar cells that produce the milk. The basal cells allow the circulation of the milk from the alveoli to the nipple region through their contractile properties. During pubertal mammary gland expansion and adult life, distinct pools of unipotent stem cells replenish the basal and luminal lineages independently of each other’s. However, it remains unclear how mammary gland initially develops. Are embryonic mammary gland progenitors multipotent, meaning that their progenitors are capable of giving rise to both basal and luminal cells? If so, when does the switch from multipotency to unipotency occur? And what are the molecular mechanisms that regulate multipotency and basal and luminal lineage segregation?

In a new study published in *Nature Cell Biology*, research team led by Prof. Cédric Blanpain, MD/PhD, WELBIO investigator and Professor at the Université Libre de Bruxelles, Belgium, identified the mechanisms that regulate mammary gland development. Using a combination of lineage tracing, molecular profiling, single cell sequencing and functional experiments, Aline Wuidart and colleagues demonstrated that mammary gland initially develops from multipotent progenitors during the early steps of embryonic mammary gland morphogenesis whereas postnatal mammary gland development is mediated by lineage-restricted progenitors.
To understand the molecular mechanisms regulating multipotency during embryonic development, the researchers developed a novel strategy to isolate embryonic mammary gland progenitors, and assessed for the first time their molecular features using single cell sequencing in collaboration with KUL researchers. Interestingly, only embryonic mammary gland progenitors and not adult cells, expressed a hybrid transcriptional signature comprising markers for both luminal and basal lineages, explaining their multipotent fate at this stage of embryonic development.

Breast cancer is the most common cancer among women. By analyzing the early steps of breast cancer formation, Alexandra Van Keymeulen and Cédric Blanpain previously demonstrated that the expression of one of the most frequently mutated genes in patients with breast cancers reactivates a multilineage differentiation program in adult unipotent stem cells. In this new study, the researchers show that embryonic mammary gland progenitors express the same genes than during the reactivation of multipotency associated with breast cancer development. “It was really interesting to see that many genes found to be specifically expressed by embryonic mammary gland progenitors are expressed in aggressive human breast cancers with poor prognosis, further suggesting that the reactivation of a gene expression program characteristic of embryonic mammary gland progenitors during tumorigenesis is essential for tumour growth and invasion.” Comments Cédric Blanpain, the senior author of this study.

In conclusion, this new study identifies multipotent embryonic stem cells of the mammary gland, uncovers the molecular features associated with embryonic progenitor multipotency and identifies the molecular mechanisms regulating the switch from multipotency to unipotency during mammary gland development. The paradigm uncovered in this study has important implications for the understanding of the development of other glandular organs and tissues such as the prostate that present similar developmental switch from multipotency to unipotency during their postnatal development. Finally, the mechanisms uncovered here have also implications for breast cancer development.

This study was a collaboration between the group of Thierry Voet KUL and the Blanpain group ULB. This work was supported by the TELEVIE, WELBIO, the Fondation Contre le Cancer, the ULB fondation, Fonds Erasme, the foundation Baillet Latour and the European Research Council (ERC).
